ABSTRACT

The semi-empirical algorithm of [1] for the estimation of turbidity (T) from marine reflectance (ρ_w) is calibrated and validated using a large dataset of *in situ* measurements collected in various waters, for use with any ocean colour hyperspectral sensor, and with Sentinel-2, Landsat 8 and Pléiades spectral bands. The relationship between particulate backscattering coefficient (b_{bp}) and side-scattering (T) is investigated through simulation of Fournier-Forand phase functions, assuming variable particles size and composition, and through T and b_{bp} *in situ* measurements in clear to extremely turbid waters.

1. INTRODUCTION

In-water suspended particulate matter concentrations (SPM) is of interest in various oceanographic research fields (e.g. underwater light attenuation and visibility, sediment transport modelling) and can be mapped from satellites.

Since several decades, remote sensing algorithms have been developed to retrieve SPM from marine reflectance (ρ_w) in open ocean case 1 waters, and later in coastal waters with complex optics. However, these algorithms show large uncertainties when applied to waters with specific inherent optical properties (SIOPs) different from those assumed in the algorithms.

Water turbidity, T, a measurement of particles side-scattering, has been demonstrated to be not only a good proxy to SPM [2], but also to be highly correlated to marine reflectance in the red and near infrared spectral ranges, e.g. [1]. Moreover, Dogliotti et al. (2015) [3] found that the relationship between T and ρ_w is only weakly sensitive to the natural variability of SIOPs and to the particulate scattering phase function.

2. DATA AND METHOD

Above water and in-water measurements have been carried out in various coastal waters around the world from 2007 to 2015 (Fig. 1): the southern North Sea (SNS) -including measurements in the Scheldt Estuary (SC est.) and in the Belgian port of Zeebrugge (ZB)-, the Mediterranean Sea (MS), the Scheldt River (SC), the Gironde (GR) and Río de la Plata (RP) estuaries and in the French Guiana coastal waters (FG). Supplementary in water measurements were performed in Belgium and France: in May 2015, at the Senne Canal (S1) and Senne River (S2) located in Machelen, north of Brussels, and at two pontoons along the Scheldt River denoted P1 (in Kallebeek), and P2 (in Antwerp), in July 2015 at MOW1 located in the southeast of the port of Zeebrugge, in the SNS; during February 2016, in the Rhône River plume (denoted RE), south of France (Fig. 1). A summary of measurements per site is given in Tab. 1.

2.1. Radiometric measurements

Radiometric measurements were performed simultaneously with water sampling and/or in water measurements in the southern North Sea using the above-water Trios (Rastede, Germany) Optical Systems (TRIOS), composed of three RAMSES hyper-spectral spectroradiometers, where simultaneous measurements of the above-water downwelling irradiance (Ed), the upwelling radiance ($Lsea$) and the sky radiance ($Lsky$) were acquired to estimate the water-leaving reflectance (ρ_w) as $\rho_w = (Lsea - rf\ Lsky)/Ed = Lw/Ed$, where rf accounts for the fraction of refracted $Lsky$ at air-sea interface (Fresnel reflectance), and is estimated from wind speed [4] in clear sky conditions, and set to 0.0265 in overcast conditions [5]. The sites FG, MS [6], SC, GR and RP [3], were also monitored using the same radiometric instruments, following the protocol of [5]. A set of 338 measurements were available after further quality-control of the data to insure low variability of sky conditions and of the water mass: the coefficients of variation, CV -defined as the ratio of the standard deviation by the average-, of $Lsky/Ed$, $Lsky$, Lw and ρ_w over the 5 best scans selected at each station, are less than 25%.

2.2. In water measurements

Simultaneously with radiometric measurements, samples were collected for estimation of T and SPM at stations within the sites in Tab. 1.a. Turbidity and SPM measurements are further quality checked using the

criteria $0.5 < SPM/T < 1.5$ g m^{-3} FNU^{-1}, which removed less than 5% of measurements. Turbidity and in water continuous measurements of optical sidescattering and backscattering were performed at the sites listed in Tab. 1.b.

Turbidity was obtained using the portable HACH 2100P/Q ISO7027 (1999) turbidimeters which measure the ratio of light emitted at 860nm and scattered at 90° to the transmitted light, this turbidity is given in Formazin Nephelometric units (FNU).

In water continuous measurements were carried out using the following optical instruments:

- Hydroscat-4 (HOBI Labs), denoted by HS4, measures the spectral backscattering coefficients b_b (m^{-1}) over scattering angles [100°-160°] centered around 140°, and at four wavelengths. In this paper, only b_{b850} (at 850nm) is used, for comparison with OBS b_{bB} measurements.

- The optical backscatter OBS500 (Campbellsci), referred to hereafter by OBS, measures the side-scattering (b_s, at 90°, in FNU) and backscattering (b_{bB}, between 125° and 170°) in Formazin Backscatter Units (FBU), using a LED emitting light at 860nm.

- The Laser In Situ Scattering and Transmissometry, LISST-100X type C (Sequoia Scientific), is used for the estimation of particles size distribution (PSD). Note that the LISST was deployed only at the Rhône River plume site.

The OBS provides average values and standard deviations, minima and maxima for b_s and b_{bB} over 1 min. The HS4 was set to measure b_b at a rate of 2 scans per second. These data were further quality controlled and processed to a) reject the first and last scans at each station and measurements taken at less than 10 cm depth (remove bubbles affect), b) correct HS4 for particles absorption along photon pathlength, using the improved sigma-correction method for turbid waters [7], c) reject negative or unrealistic data, and average HS4 data over 1 min windows, d) remove OBS and HS4 data with CV exceeding 25% over 1 min window. The last mentioned quality control mainly removes air bubbles effects due to emerging or moving the sensor out of the water.

The random shape inversion matrix was used to estimate the volume concentration ([VC_i] in µl/l) from LISST measurements, in each size class i. The Junge parameter, γ, was computed following [6], with the number of particles, N(D_i) in a given size class i estimated from [VC_i], the particles diameter (D_i) and size classes $\Delta D_i = D_i - D_{i-1}$ ($2 \leq i \leq 31$) as follows [8]:

$$N(D_i) = \frac{[VC_i]}{\frac{3}{4}\pi D_i{}^3 \Delta D_i} \times 10^{24} \qquad (1)$$

Table 1: a) Stations above- and in-water measurements sites, years, parameters, their $Median_{min}^{max}$ values, and number of stations (N); b) Continuous in-water monitoring sites, years, parameters, their $Median_{min}^{max}$ values, and number of days of measurement (D).

2.3. Turbidity model calibration

Using the turbidity model [1], type II linear regression analysis are performed on a subset of 162 turbidity and TriOS hyperspectral $\rho_w(\lambda_i)$ measurements, for λ_i ranging from 550 to 885nm, with a step of 2.5nm, and on a similar subset where TriOS reflectance spectra were convoluted with Sentinel-2 MSI, Pléiades and Landsat8-OLI sensors spectral response functions. To apply linear regression analysis, the independent variable $\rho_w(\lambda)$ is transformed into $X(\lambda)$ as follows:

$$X(\lambda) = \frac{\rho_w(\lambda)}{1 - \rho_w(\lambda)/C(\lambda)} \qquad (2)$$

with values of $C(\lambda)$ set as tabulated in [1], and set equal to 1.20 times the maximum reflectance measured, if these latter exceed values in [1] (to avoid model reaching its asymptote). The model is re-written as:

$$T = A(\lambda)X(\lambda) + B(\lambda) \qquad (3)$$

Figure 1. The locations of measurements within a) SNS, SC est., SC, GR, MS sites monitored from 2007 to 2015 (a, right), in the Senne and Scheldt Rivers on May 2015 (a, left), and of RE (Rhône River plume) on February 2016; b) RE site (zoomed): the red, yellow and green stars represent stations where simultaneous measurements of OBS and LISST are available (different colours used for different distances from the River mouth), the grey colour is where only LISST measurements are available. The ellipses delimit the three zones Z1, Z2 and Z3 (see text for details); and c) FG and RP sites, with the red (green) squares showing locations of reflectance and turbidity measurements used for calibration (validation) of turbidity algorithm, and the white triangles the locations of LISST, OBS and HS4 measurements.

To validate the calibrated model, the second independent subset of 176 measurements of T and $\rho_w(\lambda_i)$ is used, if which 153 measurements (87%) were made in highly to extremely turbid waters $T>10$FNU.

2.4. Fournier-Forand simulations

Fournier-Forand simulations are performed to obtain volume scattering functions (VSF) for refractive indices, r_i, varying in 1.01 to 1.54 encompassing the ranges of inorganic and organic particles [9], and for Junge coefficients, γ, in [3.1-5.0], covering the ranges found in case1 and case2 waters [6]. From these simulations, assuming spherically shaped particles, the ratio b_s/b_b is obtained at each couple (r_i,γ). The aim is to examine the distribution of the modelled b_s/b_b versus (r_i,γ), to understand the distribution of the *in situ* b_s/b_{bB} versus the Junge parameter estimated from LISST measurements.

3. RESULTS AND DISCUSSION

The results of turbidity algorithm calibration and validation are presented (3.1), the relationships between the side- and back-scattering coefficients are addressed for the different field measurements (3.2), and the variation of the b_s/b_b ratio is investigated from *in situ* measurements and Fournier-Forand simulations (3.3).

3.1. Turbidity model results

Tab. 2 lists the calibration coefficients A and B, the coefficient C and the coefficient of determination of the goodness of fit of the regression curves, R^2, for the turbidity model (Eq. 2-3), for wavelengths ranging from 600 to 885nm. A similar table is provided for the bands of the three sensors Sentinel2-MSI, Pléiades and Landsat-8 OLI (Tab. 3).

The hyperspectral calibration gives the best fitting curves for T and the associated ρ_w in the near infrared spectral ranges 720-730nm and 790-820nm, with $R^2 \geq 93\%$.

The validation of the models using the full range of the validation subset yields mean absolute percentage errors (MAPE) higher than 45%, for all wavelengths, because of the larger scatter of data in the low turbidity range (due to higher reflectance measurements uncertainties in clearer waters). When the validation is performed using the reduced subset over $T>10$FNU, MAPE decreases to 33-34% at 720-732.5nm and to 32-34% to 777.5-825nm. An example of calibration curve and validation is shown in Fig. 2. At shorter wavelengths $\lambda<690$nm, the effects of absorption by algae particles on reflectance decrease the performance of the turbidity model that assumes low variability of particles backscattering to absorption ratio [3]. At longer wavelengths $\lambda>830$nm, the uncertainties of reflectance measurements likely due to Fresnel correction propagate to the turbidity model.

3.2. Side- and back-scattering measurements

The OBS side-scattering b_s and HACH turbidity, T, measurements are highly correlated, at all sites (not shown here).

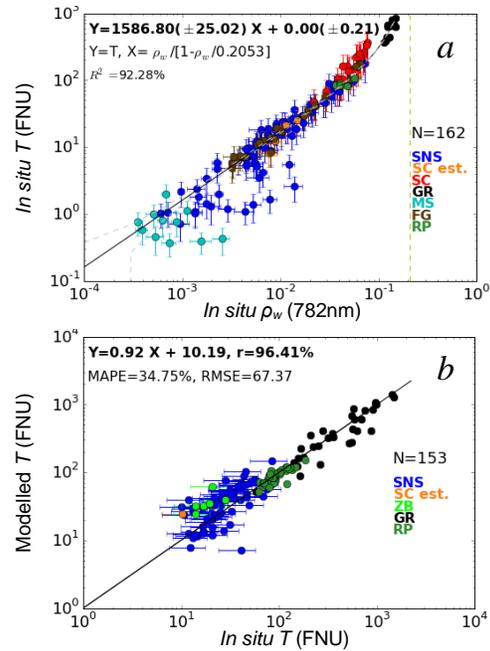

Figure 2. a) Turbidity model curve superimposed to in situ *turbidity versus* in situ *reflectance at Sentinel-2 MSI band 782nm; b) the modelled* T *versus* in situ T, *and associated regression line. The colours follow the colour of sites in the key.*

The backscatter coefficients b_{bB} and b_{b850} measured respectively by OBS and HS4 exhibit very good agreement during continuous measurements, at the Senne (SR1, SR2), Scheldt pontoon (P1, P2) and Río de la Plata River sites (Fig. 3).

The b_{bB} and b_b from all sites (Fig.4.a) have a strong correlation r=0.99. Except for measurements in the clearest waters (b_{bB}<2FBU), the two backscattering coefficients are linearly related. The OBS b_{bB} measured

at 860nm, integrated over a range of scattering angles slightly different than the scattering angles of HS4, and calibrated in reference to Formazin, is convertible to the b_{b850} (in m^{-1}) through the relationship:

$$b_{bB} = 76.6\, b_{b850} + 0.06 \qquad (4)$$

Over the range of optical backscatter $0.2 \leq b_{bB} \leq 200$FBU, Eq.4 predicts b_{bB} from b_{b850} with MAPE=6.4%, and for higher turbidity $b_{bB} \geq 10$FBU, MAPE drops below 5%.

The ratio b_s/b_{bB} from continuous measurements varies significantly within each site, and between the sites: its median values range from 1.46 in Río de la Plata and the Senne River (SR2) to 2.15 in the Senne Canal, while very similar values (~1.70) are found in the SNS and the Scheldt River, and slightly higher value (1.90) at the Rhône River plume site. The average b_s/b_{bB} for all sites is 1.72.
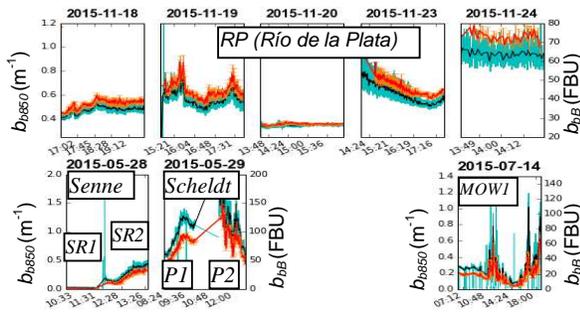

Figure 3. Continuous 1min-averaged measurements of b_{bB} and b_{b850}, respectively in red and black, and their standard deviations in orange and cyan, at Río de la Plata (top), the Senne (SR1, SR2) and Scheldt (P1, P2) locations (bottom left) and at MOW1 (bottom right).

Fig.4.b shows the variability of b_s/b_{bB} in terms of b_s. At high turbidity ranges ($b_s>30$FNU) b_s/b_{bB} generally increases with increasing b_s. In clearer waters ($b_s<2$FNU), the OBS backscattering coefficient approaches zero, yielding larger uncertainties in the estimated b_s/b_{bB}. In the medium turbidity range (2 to 30FNU) the ratio spans 3 folds from 1.2 to 3.0, where higher ratio values are associated to lower turbidity.

In the following, the ratio b_s/b_{bB} at the Rhône River plume site is examined, as regards the spatial distribution (indicating particles type/composition) and particle size distribution.
The ratio b_s/b_{bB} is highly correlated with b_s, in the low range $b_s < 20$FNU (Fig.5.a), increasing from 1.36 to 2.43. For higher turbidity $b_s \geq 20$FNU, b_s/b_{bB} varies slightly around 1.8.

The general distribution of b_s/b_{bB} in terms of γ (Fig.5.b) suggests *in situ* particles have refractive indices significantly lower than the Mie-theoretically estimated refractive indices for similar ranges of b_s/b_b. The use of

the random-shape inversion model in our calculation of γ likely has limited the overestimation of small particles concentration, as obtained from Mie-based model (not shown here) [10].

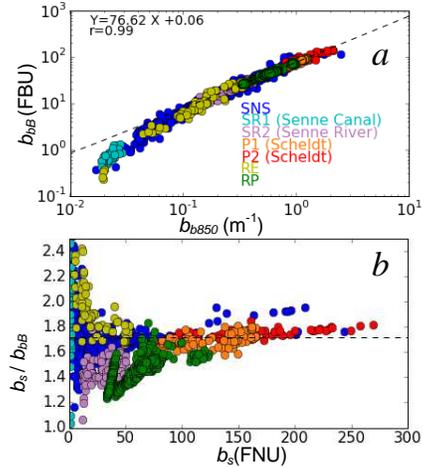

Figure 4. From OBS and HS4 (station and continuous) measurement sites: a) b_{bB} versus b_{b850}, b) the ratio b_s/b_{bB} versus b_s.

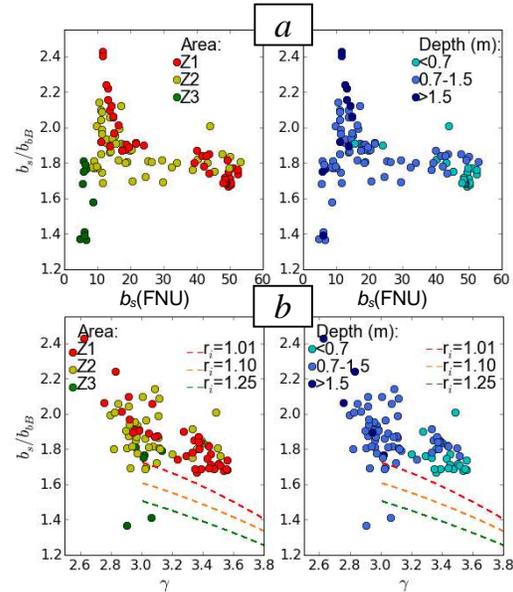

Figure 5. a) The ratio b_s/b_{bB} versus b_s from in situ measurements at RE site, b) b_s/b_{bB} versus Junge parameter γ, estimated from in situ measurements at RE (coloured circles), and b_s/b_b versus γ from Fournier-Forand simulations at three refractive indices (dashed lines). The colours of the symbols relate the positions of stations as in Fig.1 (left) and to measurement depth (right).

In the areas Z1 and Z2, sediment particles from terrigenous origin (river load) are more likely to dominate, while coarser algae-dominated particles

dominate in the area Z3 (the farthest from the Rhône estuary) [11] which is corroborated by Fig.5.b: the variation of the simulated b_s/b_b in terms of refractive indices suggests that particles in Z1-Z2 have generally higher refractive indices than the particles in Z3. The measurements in Z1 present relatively more particles with small size ($\gamma>3.3$) than in the area Z1.

Very low γ values are obtained from measurements in the three Rhône zones Z1-Z3, down to 2.6, which is lower than the values reported for the open sea, but agree with estimations reported for coastal waters [8]. Discarding out-of-range finer particles (<2.7µm) from γ calculation could have affected the accuracy of LISST derived PSD, shifting γ towards smaller ranges (larger particles concentration). On the other hand, higher values up to 3.56 were estimated mostly from measurements made just below the water surface (depth≤0.7m). Note that these high γ values may have been biased by stray light effects encountered near the sea surface [12], [13].

Fig.6 presents the ratio b_s/b_b obtained from the simulated VSF. The b_s/b_b decreases at a rate of 56% from 1.70 to 0.75 with γ increasing from 3.2 to 5, for particles with small refractive indices (<1.1). For higher refractive indices the variability of b_s/b_b value for increasing γ is slightly reduced (e.g. 48% at $r_i=1.3$, and 45% at $r_i=1.53$). For high $\gamma>4.8$, b_s/b_b values almost do not vary with increasing refractive index (only by a factor less than 5%), and that variation increases slowly with decreasing γ. In the lower range, $\gamma<3.4$, the maximum percentage variation of b_s/b_b is 20%.

While the refractive index is the main factor that impacts the backscattering ratio b_b/b, where b is the total scattering coefficient [14], [15], our simulations indicate that the particle size distribution is rather the main factor contributing to variations in b_s/b_b.

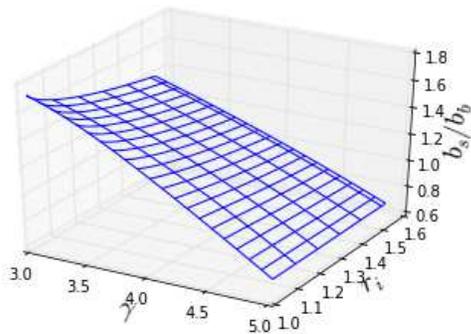

Figure 6. The ratio b_s/b_b estimated from Fournier-Forand scattering phase function, in terms of the Junge parameter and the refractive index.

4. CONCLUSION AND PERSPECTIVES

The turbidity model [1] is recalibrated and validated proving its applicability to a large range of turbidity from moderate to extremely turbid waters (10-1500FNU). The calibration coefficients are provided for a hyperspectral sensor as well as for the Sentinel-2 MSI, Pléiades and Landsat8 OLCI sensors.

The relationship between *in situ* side- and back-scattering coefficients shows a large variability of the ratio b_s/b_b in the lower turbidity range (<20FNU). Nevertheless, this variability decreases drastically with increasing turbidity indicating the predominance of particles with less heterogeneity as regard their type/composition and size. Simultaneous OBS and LISST measurements shed light on the important part played by PSD in the variability of b_s/b_b: particles from the same areas (indicating similar origin, type and composition) exhibit a b_s/b_b ratio which decreases with increasing Junge power, i.e. with finer particles that dominate the water mass. This is corroborated by Fournier-Forand simulations, which further indicate that for a given particle size, b_s/b_b decreases with increasing refractive index.

For *in situ* measurements, accurate retrieval of PSD and refractive indices can be performed by means of improved models for inversion of the volume scattering function, with a better representation of various shapes of particles e.g. [16].

From a remote-sensing perspective, the retrieval of the side-scattering coefficient (using a turbidity model) and backscattering coefficient (by inversion of the reflectance model, e.g. QAA model) from marine reflectance can help providing information on particles refractive index, by inspecting the variability of the side- to back-scattering ratio with particle size.

River plume site.
